Abstract. Bioclimatic envelope models use associations between aspects of climate and species' occurrences to estimate the conditions that are suitable to maintain viable populations. Once bioclimatic envelopes are characterized, they can be applied to a variety of questions in ecology, evolution, and conservation. However, some have questioned the usefulness of these models, because they may be based on implausible assumptions or may be contradicted by empirical evidence. We review these areas of contention, and suggest that criticism has often been misplaced, resulting from confusion between what the models actually deliver and what users wish that they would express. Although improvements in data and methods will have some effect, the usefulness of these models is contingent on their appropriate use, and they will improve mainly via better awareness of their conceptual basis, strengths, and limitations.

Key words: biodiversity; biogeography; climate change; climate envelopes; conservation planning; ecological niches; invasions; niche conservation; restoration ecology; species distributions; translocation experiments; uncertainty in prediction.

INTRODUCTION

Bioclimatic envelope models—also known as “ecological niche models,” “habitat suitability models,” or “species distribution models”—**use associations between aspects of climate and known occurrences of species across landscapes of interest to define sets of conditions under which species are likely to maintain viable populations.** Although correlational in nature, these models offer an important capacity for studies in ecology and biogeography. Once envelopes are estimated, they can be applied to a variety of interesting questions, including discovery of new populations (e.g., Feraud and Peterson 2002, Bourg et al. 2005), discovery of previously unknown species (e.g., Raxworthy et al. 2003), conservation planning (e.g., Williams et al. 2005, Wilson et al. 2005a, Araújo et al. 2011a), assessment of potential geographic ranges of invasive species (e.g., Broennimann et al. 2007, Peterson et al. 2008b, Villemant et al. 2011), mapping risk of disease transmission (e.g., Peterson et al.

2006, 2007), forecasting effects of climate change on species' distributions (e.g., Thuiller et al. 2005, Araújo et al. 2006, Huntley et al. 2008, Lawler et al. 2009) and on phylogenetic diversity (Thuiller et al. 2011), and identifying historical refugia for biodiversity (e.g., Waltari et al. 2007, Carnaval and Moritz 2008, Vega et al. 2010). Numerous recent reviews have been published on different aspects of this field (e.g., Guisan and Thuiller 2005, Araújo and Guisan 2006, Heikkinen et al. 2006, Latimer et al. 2006, Araújo and New 2007, Austin 2007, Jiménez-Valverde et al. 2008, Thuiller et al. 2008, Elith and Graham 2009, Elith and Leathwick 2009, Nogués-Bravo 2009, Huntley et al. 2010, Miller 2010, Pereira et al. 2010) and the topic has seen discussion in “perspectives” articles (Araújo and Rahbek 2006, Thuiller 2007), edited books (Scott et al. 2002), and textbooks (Franklin 2009, Peterson et al. 2011).

In short, this approach to species-level biogeography and ecology now ranks among the most widely reviewed topics in the ecological literature. Despite the great number of syntheses and the rapidly increasing numbers of primary research papers being published, much debate still surrounds the usefulness of the approach (e.g., Hampe 2004, Akçakaya et al. 2006, Botkin et al.

TABLE 1. Some of the designations in the literature about correlative models exploring the relationship between species occurrences and environmental predictors, and their implications for interpretation of the results.

Designation	Implications
Bioclimatic envelope models (or species–climate envelope models)	Term expressing that a multivariate space of climatic variables (the envelope) best matching observed species' distributions is being estimated. The term "envelope" also has been also used to refer to multivariate approaches using presence-only data, but all models constructing a multivariate space of predictor variables can be said to generate an envelope. The words "climate" or "bioclimatic" can be limiting as species may relate to other environmental covariates; more general terms, such as "abiotic" or "environmental envelope" overcome this limitation.
Ecological niche models (or climatic niche or niche models)	Expresses ideas analogous to those of "environmental envelope models," but instead of providing descriptive terminology, an attempt is made to link the envelope to elements of ecological niche theory rooted in the early work of Grinnell and Hutchinson. The link between description of pattern and niche theory has raised controversy, but progress is being made toward consensus.
Habitat-suitability models	Related to "envelope" or "niche" because it refers to the suitability of areas for species rather than actual distributions. "Habitat" emphasizes the physical space where species live and the resources it can use. As such, it opens the door for incorporation of resource variables and biotic factors that are often absent from models. The term is mostly used by researchers working at landscape scales because there resolutions are those at which such connections are more easily achieved.
Species-distributions models	Term implying that the geographic distribution of the species is the quantity modeled. Most such applications, nonetheless, characterize the multivariate environmental space delimiting species' distributions, and then project this subset of environmental space back onto geography. Important mechanisms, such as species dispersal, establishment, and biotic interactions are not accounted for. If only suitability is modeled, a species-distribution model (termed as such) will estimate something more closely related to the potential distribution, and will be exposed to criticism of being based on implausible assumptions and often contradicted by empirical evidence.

2007, Dormann 2007, Sinclair et al. 2010). Criticism has typically focused on two principal contentions: (1) that models are based on implausible assumptions, and (2) that model projections are contradicted by empirical evidence.

This paper discusses these two areas of contention, and proposes that criticisms have often been misplaced, resulting from confusion between what information the models in truth deliver vs. what users think or wish that they would express. We propose that much of the confusion arises from lack of a rigorous conceptual framework for discussions, which has produced considerable semantic ambiguity (see Table 1; see also Kearney 2006, Franklin 2009, Miller 2010, Peterson et al. 2011). In effect, an incomplete grasp of fundamental concepts underpinning the models leads to significant misapplications and misinterpretations in significant portions of the literature. Although improvements in both the data and the modeling methods that are available (Thuiller et al. 2008, Brook et al. 2009, Chevin et al. 2010, Gallien et al. 2010) will have some effect, the usefulness of these models is highly contingent on their appropriate use; hence, the situation will improve most with better awareness of the conceptual bases and consequent strengths and limitations of these models.

Are models based on implausible assumptions?

Bioclimatic envelope models are based on several assumptions, some of which find strong support in ecological and evolutionary theory, while others should be better treated as "working assumptions," as they are simplifications required for building models, rather than

rigorous assertions. Perhaps the most important theoretical assumption of these models is that species' distributions are determined wholly or partly by aspects of climate.

Climate, both at present and historically, governs at least the broadest outlines of distributions of species and biomes. Some might question whether the scale (e.g., Randin et al. 2009) or particular variables (e.g., Ashcroft et al. 2011, Austin and Van Niel 2011, Triviño et al. 2011) employed in a given application are appropriate, but these issues are more practical than fundamental in nature. Others have suggested that the assumption that climate determines species' distributions is neither supported nor contradicted by data (e.g., Bahn and McGill 2007, Beale et al. 2008, Chapman 2010). These criticisms are bold, as they fly in the face of the long-established idea that climate governs species' ranges at broad extents (e.g., Von Humboldt and Bonpland 1805, Whittaker 1975, Woodward and Williams 1987, Gaston 2003, Thomas 2010). Modern evidence that climate determines species' distributions comes from at least two independent sources: (1) distributional limits of species match particular combinations of climate variables, and (2) these limits shift through time in synchrony with changes in climate. For example, Root (1988) showed that northern limits of winter ranges of birds in North America were consistently associated with minimum winter temperatures. Similarly, Walther and colleagues (2005) showed that northern range limits of the European holly *Ilex aquifolium* were associated the 0°C degree winter isotherm, and this species' range was tracking increasing temperatures through time by

shifting distributions northwards. Corresponding upslope shifts in range boundaries along elevation gradients have also been detected both at the trailing and leading edges of distributions across elevation gradients (e.g., Wilson et al. 2005b, Lenoir et al. 2008), although patterns at the trailing edges might be often confounded by non-climatic factors (e.g., Colwell et al. 2008, Anderson et al. 2009, Hampe and Jump 2011). Evidence of contemporary range shifts matching ongoing changes in climate has been found in several taxa (e.g., Parmesan and Yohe 2003, Root et al. 2003, Hickling et al. 2006, Lenoir et al. 2008) and biomes (Gonzalez et al. 2010), and similar inferences were provided—and successfully tested—for biota in response to past climate changes (e.g., Hill et al. 1999, Araújo et al. 2005b, Green et al. 2008, Tingley et al. 2009, Dobrowski et al. 2011).

Failure to demonstrate clear species–climate associations can arise for several reasons. In the first place, the associations might have been assessed with distributional data that are incomplete or at inappropriate spatial resolution or extent. For example, Beale and colleagues (2008) evaluated climatic determination of European bird species' ranges, and purported to find negligible climatic determination; however, a parallel study using identical methods but improved distributional data for European bird species (Araújo et al. 2009) found widespread climatic determination. An analogous study applied to North American birds but conducted at an extent that included much more endemism (Jiménez-Valverde et al. 2011a) also found strong evidence of climatic determination in the distributions of birds. Failures of attribution may also arise because the climatic variables selected are not those directly limiting the distribution of the species in question (e.g., Ashcroft et al. 2011, Austin and Van Niel 2011), as will frequently be the case with species having distributions that are structured by barriers to dispersal or by factors operating at different spatial extents or resolutions from those used in modeling. Variables used in calibrating models are generally only surrogates for the variables that affect species' distributions directly via physiological mechanisms (e.g., Austin 2007, Austin et al. 2009), so poor choice of variables for incorporation into models can affect the observed associations between species' ranges and climate. Finally, the operational formulation of null models used to examine and characterize range–climate relationships may constrain results (Fig. 1; Aspinall et al. 2009), and may frequently trade Type I errors (rejecting a correct null hypothesis of no association between species distributions and climate) for Type II errors (failing to reject an incorrect null hypothesis).

Perhaps more controversial is the assumption that species' distributions will frequently be at equilibrium with climate—that is, that species inhabit the entire spatial footprint of their habitable conditions. This assumption is known to be unrealistic (e.g., Peterson et al. 1999, Svenning and Skov 2004, Araújo and Pearson

2005, Duncan et al. 2009, Monahan 2009), since dispersal often constrains the potential of species from accessing some habitable areas, and biotic interactions, including human impacts, may further prevent establishment in some areas (Fig. 2). For example, a study quantifying range filling (i.e., the degree to which observed distributions match potential ones) among European trees (Svenning and Skov 2004), as a surrogate for species' equilibrium with climate, revealed that species in northern Europe had distributions in greater equilibrium than species in southern Europe. The authors interpreted the result in relation to the historical contingencies (e.g., presence of glacial refugia and dispersal limitation) known to affect distributions of species in the south. Another study, which overcomes the circularity of quantifying species–climate equilibrium using range filling of potential distributional areas, used physiologically derived estimates of the fundamental niche (Fig. 2), for a small number of bird species in North and South America, and compared them with estimates of the realized niche, i.e., the fundamental niche reduced by dispersal, biotic interactions, and the availability of conditions across real landscapes (Monahan 2009); results were consistent with species' distributions not being in direct physiological equilibrium with climate.

The assumption of equilibrium is a problematic working assumption necessary for applications of correlative bioclimatic envelope models, especially when models are projected to different regions or times (i.e., transferability). We emphasize the need for such assumptions to be pondered carefully and stated explicitly. Assuring that models are calibrated across the broadest spatial (e.g., Pearson et al. 2004, Broennimann and Guisan 2008, Elith et al. 2010, Kujala et al. 2011), environmental (e.g., Mohler 1983, Araújo and Guisan 2006), and/or temporal (Nogués-Bravo et al. 2008) extents that are biologically and biogeographically justifiable will help the situation by reducing the difference between the estimated realized niche and the true fundamental niche (e.g., Barve et al. 2011). However, extrapolation (i.e., projections beyond the range of environmental values used to calibrate the models) must be treated carefully (e.g., Thuiller et al. 2004b, Fitzpatrick and Hargrove 2009, Elith et al. 2010, Araújo et al. 2011a). Alternatively, physiological tolerances of species to climate (i.e., interpreted as characterizing their fundamental niches) can be estimated either from first-principles approaches or via experiments (e.g., Kearney and Porter 2004, Elith et al. 2010, Kearney et al. 2010, Buckley et al. 2011). However, this approach is not practical for most species, which will frequently be too poorly known to permit first-principles approaches or will prove intractable for experimentation.

In studies involving transferability of bioclimatic envelopes onto different regions or changed suites of conditions, another assumption of the models is that the dimensions of these envelopes are conserved over relevant time periods (Peterson et al. 1999). The degree

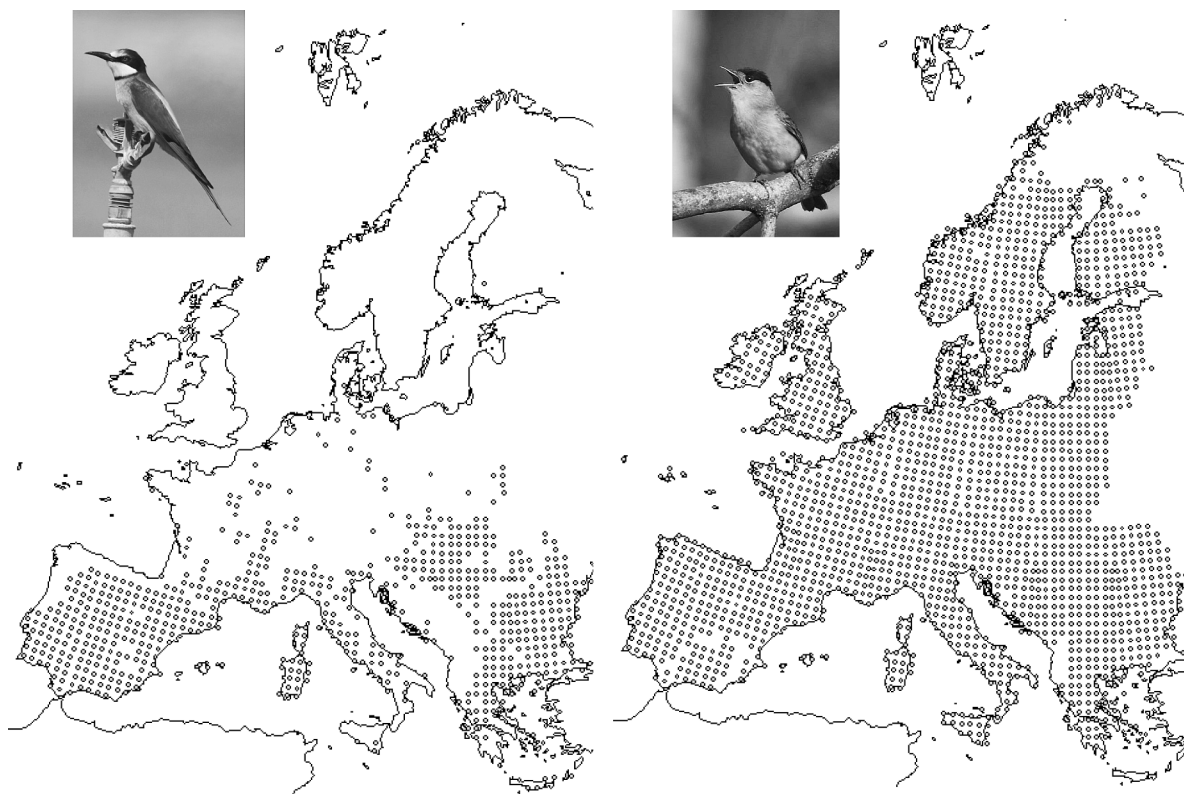

FIG. 1. Distribution of two common birds in Europe (left, European Bee-eater *Merops apiaster*; right, Blackcap *Sylvia atricapilla*). The first is a Mediterranean species that is uncommon in cooler temperate regions. The second is a widespread temperate-region species that is absent only from higher-latitude regions with subarctic climates. The scale of the grid is UTM 50×50 km. Null models comparing known geographic distributions with randomized "ranges" that preserve the spatial autocorrelation structure and leave climate data unchanged will yield random associations with climate likely to be as close as the observed ones (Beale et al. 2008). In the case of extremely widespread birds like the Blackcap, randomized distributions will resemble observed distributions closely. In the case of moderately widespread but environmentally structured species distributions, such as the Bee-eater, which has a distribution structured along a latitudinal gradient, randomized distributions are unlikely to differ significantly from them.

to which such conservatism is manifested broadly across elements of biodiversity is still a topic of debate, as rates of niche evolution and the mechanisms generating it are still poorly understood (e.g., Losos 2008, Pearman et al. 2008). The literature is often confusing with regard to the aspects of the niche that are expected to be conserved. For example, Pearman et al. (2008) noted that conservatism is achieved by stasis in the three main factors determining species' distributions (abiotic factors, biotic interactions, and dispersal), whereas non-conservatism is achieved by change in any of the three factors. However, no theoretical expectation exists for stasis in biotic interactions or dispersal: on the contrary, widespread evidence indicates that species have not always interacted with the same species as they do today (e.g., Williams et al. 2001), and they often had to move in order to track past climate changes (e.g., Clark et al. 1998). The only reasonable theoretical assumption to be made is that inherited physiological tolerances of species to environmental factors are conserved, i.e., that the fundamental niche does not change in the temporal frame involved in projections.

Studies comparing modeled bioclimatic envelopes of sister species pairs tend to find strong ecological similarity among them (Peterson et al. 1999, Martínez-Meyer and Peterson 2006, Warren et al. 2008, Hof et al. 2010), and many analyses have indicated that invasive species follow the same bioclimatic frameworks in their distributional patterns manifested on different continents (Peterson 2003). Some studies have observed differences in estimated realized niches between native and nonnative ranges of invasive species, thus inviting the interpretation that niches might have evolved in the course of the invasion (e.g., Broennimann et al. 2007, Fitzpatrick et al. 2007, Medley 2010). However, tests of conservatism (that niches change more slowly than expected from Brownian motion evolution, Losos 2008) using phenomenological approaches have at least two important limitations. Firstly, as noted above, the theoretical expectation of conservatism is justified only for fundamental niches. Estimates of realized niches typically represent subsets of the fundamental niche (Fig. 2), thus observed shifts in estimated realized niches might simply indicate that different portions of the

FIG. 2. Illustration of the relationship between the different distributional areas of a species in geographic and environmental space, and its modeled distribution and niche. In geographic space, area *A* is occupied, but the species has not been detected; area *B* is suitable, but the species was unable to colonize it due to dispersal limitation (e.g., existence of a barrier); area *C* is suitable, but species occupancy was prevented due to biotic interactions (e.g., competition). (Note that species may occur outside of suitable areas in what are termed “sink” populations). In environmental space the union of areas *D* and *E* constitutes the fundamental niche. Shaded areas around *D* comprise the realized niche; non-shaded areas around *E* identify those parts of the fundamental niche that are unoccupied. With standard strategies that evaluate predictive accuracy of models, predictions of occurrence for *A–C* are treated as errors of commission when, in fact, the model is correctly predicting the existence of suitable climatic conditions for the species. Over-fitted models will often underestimate the occupied distributional area, whereas under-fitted models will overestimate it. The figure is redrawn and modified from Fig. 2 of Pearson (2007) with permission.

fundamental niche are being occupied by the species in different regions and times (e.g., Nogués-Bravo et al. 2008, Soberón and Peterson 2011). Secondly, tests of niche conservatism based on empirical associations between observed species’ occurrences and climate are typically unidirectional. That is, similarity between estimates of realized niches compared across regions or times is consistent with the hypothesis that fundamental niches remained unchanged (Peterson et al. 1999, Martínez-Meyer and Peterson 2006, Rodríguez-Sánchez and Arroyo 2008), but failure to demonstrate such similarity does not prove the contrary, because many alternative explanations exist.

Given the theory (Wiens and Donoghue 2004, Wiens and Graham 2005) and the weight of existing empirical evidence, it is reasonable to expect that some significant degree of conservatism of the fundamental niches exists that provides predictability across taxa, environmental dimensions, and time frames considered in most studies using bioclimatic envelope models (e.g., Kozak and Wiens 2006, Peterson 2011).

Bioclimatic envelope models have also been criticized for making overly simplified assumptions about dispers-

al and biotic interactions (Dormann 2007, Zurell et al. 2009). Specifically, they have been criticized for assuming that species would either not disperse or disperse without limitations, while ignoring the role of biotic interactions in shaping current and future distributions. However, these assumptions are not integral to the models per se since the models aim only to estimate suitable conditions across landscapes, and not population processes such as dispersal (Brook et al. 2009). In reality, dispersal and biotic interactions do constrain current distributions of species; as such, they are expected to contribute to shaping the realized niche of a species and its geographic representation, particularly in constraining them from achieving full equilibrium with current climate (Fig. 2).

A very different matter is whether dispersal (e.g., Collingham and Huntley 2000, Engler and Guisan 2009) and biotic interactions (e.g., Araújo and Luoto 2007, Baselga and Araújo 2009, Meier et al. 2010) should be marshalled to constrain predictions of models when they are applied to forecasting distributional potential in different regions or under other sets of conditions (e.g., Dunn et al. 2009, Araújo et al. 2011b). These consider-

TABLE 2. The “confusion matrix” used to calculate measures of predictive accuracy for bioclimatic envelope models, with predictions classified into four categories: true presences, true absences, errors of commission, and errors of omission.

Observation	Prediction	
	Species presence	Species absence
Species present	True presence Site suitable, species present	Error of omission Site unsuitable, species present (<i>model misspecified</i>) Site unsuitable, species present (<i>model right, data wrong</i>)†
Species absent	Error of commission Site unsuitable, species absent (<i>model misspecified</i>) Site suitable, species unrecorded (<i>model right, data wrong</i>) Site suitable, species absent (<i>model right, but incomplete</i>)‡	True absence Site unsuitable, species absent

Note: While errors of omission are often a symptom of misspecification of the model, errors of commission reflect a variety of factors, some of which are not an indication that the prediction is erroneous.

† When envelope models are established with clear links with ecological niche theory, only viable breeding populations should be modeled. If sink populations are not included in the models, then errors of omission should indicate model failure.

‡ The inference of suitability from the models is correct but factors unaccounted for in the model (e.g., dispersal and biotic interactions) can prevent the species from occupying the full extent of suitable areas for the species.

ations are of particular concern when the focus of model predictions is on the actual distributions, rather than on distributional potential more generally (Fig. 2). Dealing with dispersal and biotic interactions in such contexts is far from trivial and requires approaches that go beyond the analytical framework offered by bioclimatic envelope models (e.g., Keith et al. 2008, Anderson et al. 2009, Fordham et al. 2012).

Are models contradicted by empirical evidence?

Mismatches between observations and predictions have been recorded chiefly in studies investigating climate change impacts on species' distributions (Araújo et al. 2005a), although congruence between observed and predicted range shifts have also been demonstrated (Hill et al. 1999, Araújo et al. 2005b, Green et al. 2008, Kharouba et al. 2009, Dobrowski et al. 2011). Debate also exists as to whether models successfully estimate climatic suitability for species (Pearce and Ferrier 2001, Wright et al. 2006), although again positive examples exist (Araújo et al. 2002, VanDerWal et al. 2009b, Kearney et al. 2010). Further research is needed to understand the dimensions and implications of these mismatches and exceptions, but a more general question is whether mismatches between projections and observations represent genuine model failure (Table 2).

Projections of bioclimatic envelope models are usually evaluated via measures that weight errors of commission (i.e., predicted occurrence where the species does not occur) and omission (i.e., predicted absence where the species actually occurs) equally (e.g., Liu et al. 2005). Although more stringent tests have assessed whether observed trends in species' range shifts match predictions (Araújo et al. 2005b), here too commission and omission errors have been weighted equally. However, bioclimatic envelope models estimate potential distributions (i.e., the geographic projection of the estimated

realized niches of species), rather than the occupied distributional area of the species (Araújo and Guisan 2006, Soberón 2007, 2010, Hirzel and Lay 2008, Soberón and Nakamura 2009). Species' ranges are rarely sampled exhaustively, and many species are absent from some areas presenting suitable environments, thus creating considerable “apparent” commission error. As such, one has no objective way to discern true error of commission (as defined above) from correct prediction of habitable area in an unsampled or truly unoccupied area (Peterson et al. 2008a), unless carefully designed translocation experiments are undertaken. Balancing omission and commission errors in ways that are not necessarily even can provide useful internal guidance for modeling efforts (Anderson et al. 2003), and can help with setting more effective and informative thresholds in predictions of species' presence and absence on maps (Peterson et al. 2008a).

In the case of bioclimatic envelope models, the onus is thus on the ability to outline the spatial distribution of suitable environments for the species of interest under diverse circumstances (Jiménez-Valverde et al. 2011b). The only study known to us that has provided a direct test of the ability of correlative bioclimatic envelope models to characterize the spatial distribution of suitable areas (Kearney et al. 2010) showed that their results were comparable with the estimates of the fundamental niche estimated via eco-physiological models.

In effect, when models evaluate the suitability of particular environments for species to maintain populations with reference to a set of predictor variables, and then are evaluated against observed occurrence records, errors of commission may indicate more than failure of the model to characterize suitability correctly (Table 2). Rather, much of commission error is actually prediction of potential presence in unsampled areas, or factors not included in the modeling effort may explain the absence

of the species from otherwise suitable areas. In other words, mismatches between prediction and observation do not necessarily mean that the model is wrong, but simply that the model might be incomplete (Oreskes et al. 1994). This problem is general with modeling of environmental systems: only closed systems, such as mathematical treatments, can prove a model wrong by recording mismatch between prediction and observation. In open systems, such as the situation at hand, demonstration of agreement between observation and prediction is inherently and invariably partial (Oreskes et al. 1994, Araújo et al. 2005a).

DISCUSSION

Are bioclimatic envelope models useful?

The two areas of contention reviewed in this article coincide broadly with the benchmarks proposed by Hodges (1991), in a thoughtful essay on properties and uses of “bad” models for military combat. The author argues that bad models are those that are either contradicted by some data or are grossly implausible in some aspect they purport to represent; other bad models are conjectural, i.e., they are neither supported nor contradicted by data, either because data do not exist or because they are equivocal (Hodges 1991). Here, we have shown that criticisms leveled at bioclimatic envelope models are often debatable. Although fitting bioclimatic envelope models requires some weak working assumptions, in most cases the grounds for criticism are misperceptions of the portions of the niche being estimated by models, and the consequences of these differences for model calibration, evaluation, and interpretation (for an extended discussion see Peterson et al. [2011]).

To illustrate these principles, let us consider a few applications of bioclimatic envelopes that can be considered useful or not. For example, if models are used to estimate the potential distribution of an endangered species, perhaps in the context of a translocation experiment to save the species from climate warming, modeled climatic envelopes may be used to characterize areas to which the species can be reintroduced. In a counterexample, however, if the challenge is to estimate extinction risk for species over coming decades in the face of changing climates (e.g., Thomas et al. 2004), the models only estimate the empirical relationships between species' present-day distribution and climate variables, and use the inferred relationships to identify potential distributional areas of the species under future climate scenarios. Here, the quantity of interest (extinction risk), however, is not represented among the input data and thus is not the target of the modeling exercise (Ladle et al. 2004); the usefulness of this model is thus open to debate, because only partial evidence exists that shifting climate suitabilities within the modeled time frame could speak to the reasons for which the species might go extinct (e.g., Thuiller et al. 2004a, Akçakaya et al. 2006, Botkin et al. 2007, Hampe and Jump 2011). This pair of examples

illustrates how inappropriate application of bioclimatic envelopes can cause problems with interpretation and conclusions, emphasizing the importance of proper framing of their use in appropriate biological questions.

Cautionary notes for use of bioclimatic envelope models

Several authors have provided guidelines for correct implementation of bioclimatic envelope models. Some are specific to the modeling technique used (e.g., Breiman 2001, Elith et al. 2008, 2010, Phillips and Dudík 2008), while others are more general (e.g., Franklin 2009, Miller 2010, Peterson et al. 2011). General guidelines include strategies for the selection of appropriate predictor variables in the models (e.g., Elith et al. 2005, Heidy Kikillus et al. 2010, Ashcroft et al. 2011), the decision as to whether background or pseudo-absence data are warranted and how to select them (e.g., Phillips et al. 2009, VanDerWal et al. 2009a, Wisz and Guisan 2009), choice of methods to convert probabilities of occurrence or suitability scores into projections of species presence and absence on maps (e.g., Liu et al. 2005, Freeman and Moisen 2008, Nenzén and Araújo 2011), decisions regarding methodology for model evaluation (e.g., Hirzel et al. 2006, Raes and ter Steege 2007, Peterson et al. 2008a, Phillips and Elith 2010), and use of ensemble and consensus forecasting methodologies (e.g., Araújo et al. 2005b, Diniz-Filho et al. 2009, Marmion et al. 2009, Garcia et al. 2012). It is clear that decisions regarding the technical implementation of the models will affect their quality, a topic that has received extensive treatment and reviews elsewhere (Araújo and Guisan 2006, Heikkinen et al. 2006, Latimer et al. 2006, Austin 2007, Thuiller et al. 2008, Elith and Graham 2009). However, methodological decisions should also be contingent on the user's intent. That is, no universally correct way exists to implement bioclimatic envelope models, and modelers should be careful to adopt protocols consistent with the ecological and biogeographical situation, meeting predefined goals of the study, and nonetheless conforming to the constraints imposed by the available data.

An important set of questions must be clarified at the outset of any study using these approaches. First and most basically, one should ponder whether the model is used to investigate and understand environmental correlates of species' distributions (explanation), or whether it is used to make inferences about the details of their geographic distributions (prediction) (e.g., Elith and Leathwick 2009). If prediction is the focus, then it is important to know if transferral is involved and, more importantly, what component of the species geographic or environmental range is being estimated (Peterson et al. 2011). The most common predictions of bioclimatic models in ecology, evolution, and conservation are explored in Fig. 3, with reference to the diagram provided in Fig. 2. Below, we discuss some of these applications in more detail. Of considerable importance is the observation that many applications focus on

FIG. 3. Examples of uses of bioclimatic models and some of the most common predictions of interest associated with them. Interpretation of the figure should be made in conjunction with Fig. 2. Different shades of grey indicate that alternative predictions are made for the provided examples of use or uses. See *Discussion: Cautionary notes...* for more details.

potential and abiotically suitable areas rather than on occupied distributional areas of species.

Discovery of new populations or species

Knowledge about geographic distributions of species is incomplete; here, the prediction of interest includes areas where unknown populations of known species (A in Fig. 3) or populations of unknown species (B in Fig. 3) occur. In either case, this challenge involves using what data are available to identify areas of suitable environmental conditions (Raxworthy et al. 2003). Models may have to be kept quite simple, as occurrence data may be few (de Siqueira et al. 2009). For such uses, errors of commission from the models are not necessarily errors; typically, they are the prediction of interest (i.e., model right, data wrong; see Table 2). Little guidance is available for choosing the right balance between minimization of omission and commission errors in such cases; a practical option is to choose the highest suitability score that

achieves a certain minimum omission error (Peterson et al. 2008b) as a threshold. Models need not even be comprehensive in scope (de Siqueira et al. 2009); rather, the aim is to identify a few high-priority sites.

Reserve selection and design

The prediction of interest in most spatial conservation-planning applications is the occurrence of species in particular areas of conservation interest (the shaded area in the corresponding panel in Fig. 3). Errors of commission are generally unacceptable because they could lead to spending limited resources for conserving species where they do not occur, or where unsuitable conditions exist for the species. For this reason, applications of bioclimatic envelope models in spatial conservation planning are often conservative, and model calibration can focus on minimizing commission errors (e.g., Araújo et al. 2011a).

Restoration, translocation, or reintroductions

The common feature of models used to predict areas for restoration, translocation, or reintroductions is that predictions are not about where species are, but where they could be. Notice that the prediction of interest is often areas that are abiotically suitable for the species and free of biotic constraints for its occurrence (area *B* in Fig. 3). Such models cannot be evaluated with familiar approaches that minimize errors of omission and commission because commission (predicted presences in unoccupied locations) is precisely the prediction of interest. More promising approaches include those that generate predictions mainly focused at reduction of errors of omission (Peterson et al. 2008a) and focus on predictions of presences rather than absences (e.g., Hirzel et al. 2006, Phillips and Elith 2010).

Evaluating risk of species invasions and disease transmission

Here, the prediction of interest is usually the non-inhabited but suitable area that could be invaded (*B* in Fig. 3), particularly in the case of invasives where some dispersal barrier is generally what constrains species from achieving full distributional equilibrium. In the case of disease transmission, focus also includes actual distributions. Omission errors will frequently be not erroneous, as areas of overprediction are often what is of interest. Omission error, on the other hand, is almost always important and relevant, and so it is often minimized as much as possible. Of course, other, non-environmental factors may modify the suitability or accessibility of a site, so routes of access, presence of competitors, etc., must all be considered in comprehensive studies.

Climate change impacts on biodiversity

Among the most popular uses of bioclimatic envelope models are inferences about the possible impacts of climate change on the distributions of species. The prediction of interest can be the occupied distributional area of a species, or its potential or abiotically suitable areas for occurrence in the future (Fig. 3). If the prediction concerns occupied distributional areas, estimates of colonization rates as well as climate suitability are required, and approaches that couple bioclimatic envelope models with metapopulation models can be useful (e.g., Keith et al. 2008, Anderson et al. 2009, Fordham et al. 2012). Whether the modeler should weight errors of omission and commission equally in such cases, or down-weight errors of commission, is still a matter of debate.

Niche evolution

Increasingly, evolutionary ecologists are using bioclimatic envelope models to ask questions regarding the rates of change of niche traits across phylogenies (Wiens and Graham 2005, Peterson 2011). The prediction of interest generally includes the set of environmental

combinations that constitute the fundamental ecological niche of the species (Peterson et al. 2011). Such characterizations of fundamental niches are perilous, owing to perpetual complications with limited representation of the full dimensions of these niches on real-life landscapes (Peterson et al. 2011), and tests of niche conservatism are unidirectional in nature: evidence for niche similarity in time and space provides conditional support for the conservatism hypothesis, but if niches appear dissimilar, no firm conclusions can be drawn.

Conclusions

Ample evidence and precedent support the idea that bioclimatic envelope models can reconstruct environmental correlates of species' geographic distributions. Furthermore, the broad diversity of applications of these models indicates that they represent a potentially powerful tool in understanding whole-range geography and ecology of species. The critical question is under what specific circumstances are such models useful or not? We argue that a clear conceptual framework can place complex ideas in useful contexts and avoid worlds of confusion. In the case of bioclimatic envelope models, the criticisms that have been levelled at the approach fall into this trap: for lack of a detailed and appropriate conceptual context, the criticisms offered are not generally or broadly applicable. That is, the bioclimatic envelope modeling approach is not always guilty of the crimes of which it is accused, but rather it has frequently been guilty of not having placed results in an appropriate or sufficiently clear conceptual framework. We suggest that each application of bioclimatic envelope modeling be subjected to a careful thought process regarding key assumptions *before* the modeling program is run. The researcher must consider carefully which portions of the distributional area are being sampled, and how completely the environmental range of the study area is being characterized. What is more, the effects of biotic environments and species' mobility must be weighed in choosing that study area in the first place, and assumptions made explicitly regarding why those choices were made. Finally, the desired end product must be weighed against what the modeling exercise is actually designed to estimate. Only with such careful pondering can bioclimatic envelope modeling achieve its full potential.

ACKNOWLEDGMENTS

M. B. Araújo is funded through the FCT Range Shift project and acknowledges the Spanish Research Council (CSIC), the "Rui Nabeiro/Delta" Biodiversity Chair, and the Danish NSF for support. A. T. Peterson thanks Microsoft Research for support for this work. We thank Jorge Soberón, Richard Pearson, Rob Anderson, Miguel Nakamura, and Enrique Martínez Meyer for stimulating discussion while preparing the book *Ecological Niches and Geographical Distributions* (Peterson et al. 2011); M. B. Araújo also thanks for discussion the participants of the third Riederalp Workshop "The Utility of Species Distribution Models as Tools for Assessing Impacts of Global Change" (2008). The ideas in this review were matured over the past decade following discussions with several colleagues, and we thank them for that. Raquel Garcia, Gary

Graves, David Nogués-Bravo, and David Warton provided insightful comments on a previous version of the manuscript; we also thank Mick Ashcroft and two anonymous reviewers for their critical assessments of the manuscript.
